Risks For The Long Run And The Real Exchange Rate*

Riccardo Colacito†
Mariano Massimiliano Croce‡

Abstract

Brandt, Cochrane, and Santa-Clara (2004) point out that the implicit stochastic discount factors computed using prices on the one hand and consumption growth on the other hand have very different implications for their cross country correlation. They leave this as an unresolved puzzle. We explain it by combining Epstein and Zin (1989) preferences with a model of predictable returns and by positing a very correlated long run component. We also assume that the intertemporal elasticity of substitution is larger than one. This setup brings the stochastic discount factors computed using prices and quantities close together, by keeping the volatility of the depreciation rate in the order of 14% and the cross country correlation of consumption growth around 30%.

1 Introduction

There is a growing literature in economics that goes under the name of risks for the long run. Two fundamental forces are at work in this kind of models. Individuals care about the timing of the resolution of uncertainty and consumption is modeled as having a slowly moving predictable component. These models have been very successful in explaining some long standing puzzles of financial economics, such as the high excess return of equities over the risk free rate. Examples of these economies can be found in Bansal and Yaron (2004), Bansal, Gallant, and Tauchen (2002) and Hansen, Heaton, and Li (2004). This paper extends this framework to a two country model. Financial markets seem to indicate a high degree of co-movement in the stochastic discount factors, while the poor correlation of consumption growth across countries points in the opposite direction. Brandt, Cochrane, and Santa-Clara (2004) construct an index, that they regard as an indicator of risk sharing, that highlights this finding: when financial data are used to derive the stochastic discount factors the index is very close to one, while if we assume identical CRRA utility functions in the two countries and construct the stochastic discount factors accordingly, this index drops to 0.3. Our attack to the problem relies on the assumption that consumption growth is determined by a small, but highly persistent and cross-country correlated component. When combined with the type of preferences described before, the puzzle seems to disappear. The economic intuition is that the concept of risk sharing entails both short run and long run risk. If the latter source of uncertainty is common to the two countries and people care about the timing of the resolution of uncertainty, it is possible to reconcile a low correlation of consumption with a high degree of risk sharing.

We prefer to reformulate this puzzle without invoking the idea of international risk sharing. Following Backus, Foresi, and Telmer (1996) for any stochastic process for the depreciation rate and returns on domestic and foreign currency denominated assets, there exist pricing kernels, whose ratio is equal to the depreciation rate, provided that there are no arbitrage opportunities. This "accounting" relationship allows to retrieve the correlation of the stochastic discount factors from their volatilities and the standard deviation of the rate of growth of the exchange rate. Using the Hansen and Jagannathan (1991) bound the variance of the pricing kernels is at
least 25%, while Brandt, Cochrane, and Santa-Clara (2004) estimate the volatility of the depreciation rate between the US and three other countries to be around 14%. The implied correlation of the stochastic discount factors is not less than 0.96, when computed in this way. However data on consumption display a very low cross country correlation and the assumption of agents with identical CRRA preferences in the two countries would result in a correlation of the stochastic discount factors around 0.3. As in the equity premium puzzle literature it is impossible to reconcile the high volatility of the pricing kernel with the volatility of consumption growth unless an implausibly high coefficient of risk aversion is assumed, in an international context, CRRA preferences fail to reconcile the high cross country correlation of stochastic discount factors with the relative smoothness of the depreciation rate.

We model a two country economy, each of them populated by a representative consumer with Epstein and Zin (1989) recursive preferences. We specify both consumption and dividend growths as the sum of an i.i.d. shock and a predictable component, that we refer to as the long run term, whose magnitude is small when compared to the volatility of the consumption specific shock. Nevertheless, we impose a highly persistent autoregressive process for this component. The countries share this setup. We allow shocks to be cross country correlated. Bansal and Yaron (2004) show that in a closed economy, this setup is able to explain the realized equity premium, when the intertemporal elasticity of substitution is larger than one. In a two country economy, we show that adding highly correlated long run components can reconcile the degree of co-movement in the stochastic discount factors as measured from prices and from quantities.

The paper is organized as follows. In section 2 we describe the determinants of the puzzle that we want to explain. In section 3, we write down a simple model that we can solve and calibrate. This provides a useful instrument to show the internal transmission mechanism of the model. We then calibrate this model and show how we can match a large number of statistics in the data. In section 5, we extend the model to include assets that pay dividends and we explore what our model has to say about the correlation of the stock markets. Section 6 concludes the paper, summarizing the main findings.
2 The "international equity premium puzzle"

We analyze two economies that we denote as home \((h)\) and foreign \((f)\). Following Backus, Foresi, and Telmer (1996) and Brandt, Cochrane, and Santa-Clara (2004), no arbitrage conditions\(^1\) imply the following relationship between the log-stochastic discount factors of two economies, \(m^h_t\) and \(m^f_t\), and the log-depreciation rate, \(\pi_{t+1}\), defined as the growth of the exchange rate:

\[
\pi_{t+1} = m^f_{t+1} - m^h_{t+1}
\]

By taking the variance operator on both sides and by denoting \(\sigma_{m^i}, \forall i \in \{h, f\}\) as the standard deviation of the stochastic discount factor in the two countries, \(\rho_{m^h,m^f}\) as the correlation of the stochastic discount factors and \(\sigma_{\pi}\) as the volatility of the depreciation rate, we obtain:

\[
\rho_{m^h,m^f} = \frac{\sigma_{m^h}^2 + \sigma_{m^f}^2 - \sigma_{\pi}^2}{2\sigma_{m^h}\sigma_{m^f}} \quad (1)
\]

It is useful to restate the puzzle we are after in terms of equation (1). The Hansen and Jagannathan (1991) bound on the volatility of the stochastic discount factor is in the order of 50% in the US, United Kingdom and Germany\(^2\) and the standard deviation of the depreciation rate between the same countries is in the order of 14%. These numbers and equation (1) imply a correlation of the stochastic discount factors of approximatively 96%. Using identical CRRA preferences, the pricing kernels are \(m^i_t = -\gamma \Delta c^i_t, \forall i \in \{h, f\}\) and the correlation \(\rho_{m^h,m^f}\) is simply the correlation of consumption growth. This number is far below the 0.96 calculated from financial data and it ranges from 0.24 to 0.42 depending on the countries and on the frequency of the data, as in Brandt, Cochrane, and Santa-Clara (2004).

We can also see this as a restatement of Mehra and Prescott (1985) equity premium puzzle. It is well known that when CRRA preferences are used, a high coefficient of risk aversion, \(\gamma\), is needed to reconcile the low volatility of consumption.

\(^1\)See Backus, Foresi, and Telmer (1996) for a detailed explanation of how to derive this relationship.

\(^2\)See for example Brandt, Cochrane, and Santa-Clara (2004).
growth with the degree of volatility of the stochastic discount factor indicated by financial data. A 2% annual volatility of consumption growth would require a \( \gamma \) of 25 to obtain at least as much volatility as the Hansen and Jagannathan (1991) bound. If we specialize equation (1) to this case:

\[
\rho_{\Delta c^h, \Delta c^f} = \frac{\gamma^2 \sigma_{\Delta c^h}^2 + \gamma^2 \sigma_{\Delta c^f}^2 - \sigma_\pi^2}{2 \gamma^2 \sigma_{\Delta c^h} \sigma_{\Delta c^f}}
\]

we would need the volatility of the depreciation rate to be at least 53%, that is almost 4 times what is observed in the data. In a one country model, the stochastic discount factor should be extremely volatile to explain the equity premium. In a two country model, it is also required that the stochastic discount factors are very correlated across countries to explain the smoothness of the depreciation rate.

This opens up to the rules of the game we want to play. We want to be able to reconcile the implications that both financial and consumption data have for equation (1), by controlling at the same time for risk aversion, cross country correlation of consumption growth and volatility of the depreciation rate.

3 Setup of the economy

3.1 Structure of the markets

We study a two country endowment economy that we shall denote as home \((h)\) and foreign \((f)\). We assume that there are only two goods in the whole economy and that these goods are country specific. To further simplify the setup, we impose that preferences are such that there is complete home bias, meaning that each country is willing to consume only the good that it is endowed with. Markets are complete, implying that returns are equalized across countries after accounting for the exchange rate. An equilibrium of this economy exists, in which each country behaves as in autarky both for consumption and asset holdings.

The need for this extreme structure of the markets is dictated by the fact that we want to use preferences of the Epstein and Zin (1989) type. There exists a literature that examines the dynamics of allocations when trades in the goods market
are allowed and agents have recursive, but non time separable preferences. Anderson (2005) and Kan (1995) provide analytical and theoretical tools to study these economies. In our case, the need to also introduce a slowly moving predictable component in the endowment process would make these frameworks difficult to extend. For the sake of explanation, we prefer to study the no-trade limiting case and leave a more realistic structure of the goods market for future extensions of this paper.

3.2 Preferences and long run risks

We model the two economies as each having a representative consumer with Epstein and Zin (1989) preferences:

\[ U^i_t = \left\{ (1 - \delta)(C^i_t)^{1-\theta} + \delta \left[ E_t \left[ (U^i_{t+1})^{1-\gamma} \right] \right]^{\frac{1}{1-\gamma}} \right\}^{\frac{\theta}{\gamma}} \quad \forall i \in \{h, f\} \]

where \( \gamma \) is the coefficient of risk aversion and \( \theta = \frac{1-\gamma}{1-\gamma/\Psi} \) implicitly defines the intertemporal elasticity of substitution \( \Psi \). The two economies are assumed to be symmetric, having the same preference and transition laws parameters. The implied pricing equation for the \( j \)th asset is

\[ E_t \left[ M^i_{t+1} R^i_{j,t+1} \right] = 1, \quad \forall i \in \{h, f\} \]

where the pricing kernel \( M^i_{t+1} \) is a stochastic process that depends on consumption growth, \( \frac{C^i_{t+1}}{C^i_t} \), on the return on the asset that pays the consumption bundle, \( R^i_{c,t+1} \) and on the preference parameters:

\[ \log M^i_{t+1} = \theta \log \delta - \frac{\theta}{\Psi} \log \left( \frac{C^i_{t+1}}{C^i_t} \right) + (\theta - 1) \log R^i_{c,t+1}, \quad \forall i \in \{h, f\} \]

\[ (2) \]

In what follows, we will adopt the convention of denoting log-variables in small letters (hence \( m^i_{t+1} = \log M^i_{t+1} \)). The price of an assets that entitles to a stream of country \( i \) consumption bundle costs \( P^i_{c,t} \) and has the following gross return:

\[ R^i_{c,t+1} = \frac{v^i_{c,t+1} + 1}{v^i_{c,t}} \exp \Delta c_{t+1} \]

\[ (3) \]
with $v^i_{c,t+1}$ being the price-consumption ratio in each country $i = \{h, f\}$. We complete the system by specifying exogenous laws of motion for consumption as:

$$\Delta c_i^t = x_i^t + \varepsilon_{c,t}^i$$

$$x_i^t = \rho_x x_{i-1}^t + \varepsilon_{x,t}^i$$

$\forall i = \{h, f\}$. All shocks are iid normally distributed within each country, but they are allowed to be cross-country correlated according to the following scheme:

$$[\varepsilon_{c,t}^h \varepsilon_{c,t}^f \varepsilon_{x,t}^h \varepsilon_{x,t}^f] \sim N(0, \Sigma)$$

$$\Sigma = \begin{bmatrix}
\sigma_c^2 H_c & 0 \\
0 & \sigma_x^2 H_x
\end{bmatrix}$$

where

$$H_c = \begin{bmatrix}
1 & \rho_{c}^{hf} \\
\rho_{c}^{hf} & 1
\end{bmatrix}$$

$$H_x = \begin{bmatrix}
1 & \rho_{x}^{hf} \\
\rho_{x}^{hf} & 1
\end{bmatrix}$$

In Appendix A we show that a first order Taylor expansion of the price-consumption schedule around its steady state $\bar{v}_c^i$ is:

$$v_{c,t}^i = \bar{v}_c^i \left(1 + \frac{(\Psi - 1)}{\Psi(1 - \rho_x \delta)} x_i^t\right) , \forall i \in \{h, f\}$$

Notice that when the intertemporal elasticity of substitution $\Psi$ is larger than one, the coefficient on $x_t$ is positive. Bansal and Yaron (2004) identify this characteristic of the model as the one that allows high equity premia to be justified by a reasonable coefficient of risk aversion. Intertemporal substitution dominates the wealth effect with the consequence of a higher volatility of the return on the consumption asset.

In the Appendix we derive analytical expressions for the international correlation of the stochastic discount factors and the volatility of the depreciation rate. The following two propositions can be stated.

**Proposition 1.** For a given choice of parameters and provided that $\rho_{x}^{hf} = \rho_c^{hf}$, the lowest cross country correlation of the stochastic discount factors is achieved for

$$\Psi = \frac{1}{\gamma} \delta , \rho_x = 0 , \rho_{c}^{hf} = \rho_{x}^{hf}$$
where $\tilde{\delta} = \frac{1 - 2\rho_x \delta + \delta^2}{\delta^2(1 - \rho_x^2)}$. Furthermore, if $\rho_{x,h,f} > \rho_{c,h,f}$, then $(\Psi, \rho_x) = \left( \frac{1}{\gamma} \tilde{\delta}, 0 \right)$ is the unique minimizer.

**Proof.** See Appendix B. 

**Proposition 2.** For a given choice of parameters, the lowest volatility of the depreciation rate is achieved for $\rho_{x,h,f} = 1$.

**Proof.** See Appendix B.

Proposition 1 argues that a highly persistent $x_t$ component is needed in both countries in order to raise the correlation of the stochastic discount factors. Recent studies by Bansal, Gallant, and Tauchen (2002) and Bansal and Yaron (2004) provide estimates and calibrations of this number to a value very close to unity. Furthermore propositions 1 and 2 combined require a high cross-country correlation of the $x_t$ components as a necessary condition to increase the correlation of the discount factors and to keep the volatility of the depreciation rate at a low level. By staring at equations (4) and (5) one might be tempted to say that the quasi unit root process of $x_t$ together with the high correlation of $x_t$ across countries is guiding the result, by increasing the cross country correlation of consumption. However an explanation of our result based exclusively on the magnitude effect of $x_t$ on the cross-country correlation of consumption would completely overlook the key feature of the model and we would regard this as a failure of our analysis being the correlation of the consumption processes in the order of 30% in the data. As a consequence we will set the standard deviation of $\varepsilon_x$ to a small number to offset the impact of $\rho_x \approx 1$.

A third ingredient must to be added to the picture. Proposition 1 calls for the need of Epstein-Zin preferences to break the link between risk aversion and intertemporal elasticity of substitution. As $\delta$ and $\rho_x$ approach 1, the timing of the resolution of uncertainty becomes part of the problem and a considerable higher $\rho_{m,h,m,f}$ can be achieved. As shown in equation (2), Epstein-Zin preferences introduce an extra term in the pricing kernel that involves the return on the consumption asset and that is not present with CRRA preferences. As $x_t$ is a predictable and persistent component of consumption growth, it is going to affect crucially the stream of dividends paid by the consumption asset. Therefore it is going to be key in determining
expected value and volatility of this return. Furthermore, the fact that this long
run component is highly correlated across countries implies an extremely high cor-
relation of the new term introduced in the pricing kernel by the Epstein and Zin
preferences.

In the next section we show how it is only the combination of all the three
ingredients put forward by Propositions 1 and 2 that delivers our result.

4 Results from a calibrated economy

In this section we report the results of a calibrated economy of the type discussed
earlier. We assume that the countries share the same parametrization. Table 1 re-
ports our baseline calibration. As the structure of our two parallel economies mim-
ics those discussed by Bansal and Yaron (2004) and Bansal, Gallant, and Tauchen
(2002) most of the coefficients used in our analysis are either estimated or calibrated
in those papers. Notice that the coefficient of risk aversion $\gamma$ is relatively low com-
pared with what is commonly found in the equity premium puzzle literature and
with the number proposed by Brandt, Cochrane, and Santa-Clara (2004) in its ex-
tension to an international context. The intertemporal elasticity of substitution, $\Psi$
is equal to the one estimated by Bansal, Gallant, and Tauchen (2002) and combined
with a high persistence of the predictable component of consumption growth, $\rho_x$, is
what allows to explain the degree of equity premium observed in the data\(^3\). We set
$\rho_x = .987$, that is the value estimated by Bansal, Gallant, and Tauchen (2002) and
that is slightly higher than the 0.979 calibrated by Bansal and Yaron (2004). The
standard error of $\varepsilon_x$ is extremely small compared to the one of $\varepsilon_c$, allowing the latter
to be the main determinant of the volatility of consumption growth. The standard
deviation of consumption growth implied by our choice of parameters is 2.2%, that
is the average growth of per capita consumption of nondurables and services\(^4\) from

\(^3\)We will discuss results from an economy that includes an asset that pays dividends in a later
section.

Notes - All figures are annualized. The two countries share the same calibration.

The monthly individual discount factor is 0.998, that accounts for an annual risk free rate of 2.5%. The choice of the correlations coefficients is driven by the need of matching key features of the data. We set \( ρ_{xf} \) to 1 as suggested by Proposition 2 to keep the volatility of the depreciation rate to about 14%. The cross country correlation of the shocks to consumption is chosen so to obtain a correlation of consumption growth in the order of 30%.

In the previous section we have discussed how it is the combination of long run risks, Epstein-Zin preferences and cross country highly correlated \( x_t \) to drive the results. Table 2 shows what happens if we shut down one or more of these components at a time as compared to using all of them together. The first line of this table can be regarded as the case discussed by Brandt, Cochrane, and Santa-Clara (2004). Despite a reasonable volatility of the exchange rate, the correlation of the stochastic discount factors is extremely low, originating the puzzle that is the main attention of this paper. Clearly no combination of up to two ingredients is able to explain the puzzle and the next lines of the table seem to reinforce this idea. As we combine the three of them, as shown in the last line of Table 3, we manage to increase the correlation of the pricing kernel to 0.91 without having to increase the variance of the depreciation rate. Also notice how the volatility of consumption is kept to about 2% and the correlation of the consumption process is almost unchanged compared to what reported by Brandt, Cochrane, and Santa-Clara (2004). We regard the findings of Table 2 as the main result of the paper.

Notes - All figures are annualized. All coefficients are set to the numbers reported in Table 1, except for the parameters reported in the first three columns.

Table 3 reports the behavior of other relevant variables as we increase the persistence of the long run component. As already observed, the correlation of the stochastic discount factors is increasing and even more so the closer we get to $\rho_x = 1$. The standard deviation of consumption growth does not change too much, except for the case in which $\rho_x = 0.999$. This is the result of our choice of setting the volatility of the long run term to a tiny number compared to the volatility of $\varepsilon_c$. Indeed the ratio $\sigma_{\varepsilon_c}/\sigma_{\Delta_c}$ indicates that the contribution of long run risks to the volatility of consumption growth is always small unless $\rho_x \approx 1$. The two covariance terms that seem to be driving the results are the correlation of the consumption assets and the correlation of consumption growth and consumption asset returns across countries. As the persistence of the $x_t$ component rises, the returns on the consumption asset will mainly reflect the long run perspectives of consumption growth, implying a low correlation with $\Delta c_t$ in any country, that is driven for a large part by the short run shock $\varepsilon_c$, as we have already discussed before. By the same token, returns are going to be increasingly correlated across country as a result of our choice of setting $\rho_{hf}^b$ to one. Since these returns enter the stochastic discount factors of the two countries, a considerably higher correlation of the two can be achieved under our benchmark calibration. Last notice how our choice of setting the correlation of the long run
components to one, as suggested by Proposition 2, manages to keep the volatility of the depreciation rate to a constant 14%.

5 Other implications of the model

We introduce dividends in the model as following a process that is extremely related to the one that we have used for consumption growth:

$$\Delta d_t^i = \lambda x_{t-1} + \varepsilon_{d,t}^i, \forall i \in \{h, f\}$$ (7)

with $\varepsilon_{d,t}^i$ i.i.d. normal with mean zero and variance $\sigma_d^i, \forall i \in \{h, f\}$. The coefficient $\lambda$ is referred to as the leverage and is usually set to a number larger than 1. The six shocks of the economy follow a multivariate normal process with covariance matrix $\Sigma$:

$$
\begin{bmatrix}
\varepsilon_{c,t}^h & \varepsilon_{c,t}^f & \varepsilon_{x,t}^h & \varepsilon_{x,t}^f & \varepsilon_{d,t}^h & \varepsilon_{d,t}^f
\end{bmatrix}' \sim N(0, \Sigma)
$$

$$
\tilde{\Sigma} = \begin{bmatrix}
\sigma_c^2 H_c & 0 & 0 \\
0 & \sigma_x^2 H_x & 0 \\
0 & 0 & \sigma_d^2 H_d
\end{bmatrix}
$$
where

\[ H_c = \begin{bmatrix} 1 & \rho_c^{hf} \\ \rho_c^{hf} & 1 \end{bmatrix} \quad H_x = \begin{bmatrix} 1 & \rho_x^{hf} \\ \rho_x^{hf} & 1 \end{bmatrix} \quad H_d = \begin{bmatrix} 1 & \rho_d^{hf} \\ \rho_d^{hf} & 1 \end{bmatrix} \]

Define as \( v_{d,t} \) the price-dividend ratio at time \( t \). Appendix A shows that a log-linear approximation of \( v_{d,t} \) around its steady state \( \overline{v}_d \) is:

\[
v_{d,t} = \overline{v}_d \left( 1 + \left( \lambda \Psi - 1 \right) \frac{\Psi (1 - \rho_x \delta)}{\Psi} x_t \right), \forall i \in \{h, f\} \quad (8)
\]

The pricing kernel is not affected by the introduction of this asset and therefore it keeps the form of equation (2). What we want to study is the consequence that the parametrization of the previous section has for the volatility and cross country correlation of the returns \( r_{d,t}^i, \forall i \in \{h, f\} \). We know from the data that the annual volatility of stock markets’ excess returns is in the order of 14% and that the international correlation of financial markets can be regarded as a number ranging from 35% to 60%.5

</table>

Notes - All figures are annualized.

Table 4 reports the baseline calibration of \( \lambda, \sigma_d^i \) and \( \rho_d^{hf} \). The choice of specific numbers for the additional parameters introduced in this section follows the same logic of the economy with the consumption asset only. The volatility of the short run shock to dividend growth is the same of Bansal and Yaron (2004). Once again notice how this number is noticeably higher than \( \sigma_z^i, \forall i \in \{h, f\} \). The coefficient \( \lambda \) is set in such a way that the ratio \( \sigma_{\Delta d}/\sigma_{\Delta c} \) in the range (4,8) estimated by Ludvigson,

5Brandt, Cochrane, and Santa-Clara (2004) calculate the correlation of the US stock market with the British, German and Japanese ones to be 57%, 45% and 34%, respectively.
Lettau, and Wachter (2004). In particular, $\sigma_{\Delta d}/\sigma_{\Delta c}$ should be closer to the upper bound if we use postwar data. In our baseline calibration, we set $\lambda = 1.8$ that implies $\sigma_{\Delta d}/\sigma_{\Delta c} = 5.27$. The cross country correlation of the short run shocks to dividends, $\rho_{d}^{hf}$, is set to a value that allows us to capture an overall correlation of stock markets is in the range suggested above.

Notes - All figures are annualized. All coefficients are set to the numbers reported in Table 1 and Table 4.

Table 5 shows that our baseline calibration is able to match key features of the stock markets. The stochastic discount factors that have the property of being highly correlated produce an annualized volatility of excess returns of the assets that pay the dividend process in the order of 14%. Furthermore the cross-country correlation of the return processes is in the range we pointed out before.

6 Conclusions

We have shown that allowing for an intertemporal elasticity of substitution larger than one and for a persistent and highly cross-correlated forecastable component of consumption growth in the economy described by Brandt, Cochrane, and Santa-Clara (2004) it is possible to reconcile the measure of cross country correlation of the stochastic discount factors obtained from data on consumption and from data on prices. This result is achieved in combination with a lowly volatile depreciation rate and without requiring a high correlation of the consumption processes and coefficient of risk aversion. We have also shown how key features of the data can be described by the same parametrization that allows us to meet our primary goal, extending in

---

$^6$The sensitivity of the results to this choice of $\lambda$ is available upon request to the authors.
this way the set of properties of the models that take into account long run risks beyond what pointed out by Bansal and Yaron (2004).

Future extensions of this work should focus on providing empirical evidence for the high cross-country correlation of the long run component and on more realistic setups of the economy, in which agents in one country are willing to consume goods produced in the other country. We discussed how the presence of Epstein and Zin (1989) preferences and the introduction of the long run predictable component contribute to make this a very hard task. We remain optimistic about the main features of our setup to hold also in a more complicated setup.

Appendix A. Derivation of moments

Let’s first of all recall the list of our deeper coefficients:

$$\Upsilon = \{\theta, \psi, \delta, \rho_x, \lambda, \sigma_c, \sigma_d, \rho_c^{hf}, \rho_x^{hf}, \rho_d^{hf}\}$$

We will express our relevant moments as a function of these parameters to be able to disentangle their specific effects. We will start from the formulas for the consumption growth, then we will focus on the formulas for the relevant financial variables. Remember that we assume:

$$\Delta c_{i,t+1} = x_i^t + e_{x,t+1}^i \quad i = h, f$$

Then

$$\text{Var}(\Delta c_{i,t+1}) = \sigma_c^2 + \frac{\sigma_x^2}{1 - \rho_x^2}$$

$$\text{Cov}(\Delta c_{i,t+1}^h, \Delta c_{i,t+1}^f) = \rho_{hf} \sigma_c^2 + \frac{\rho_{hf} \sigma_x^2}{1 - \rho_x^2}$$

Now we can focus on $$v_{c,t}^i$$, just by applying the general NA condition formula to the asset that pays the entire consumption bundle. Remember that in this case the return from the asset is

$$R_{c,t+1}^i = \frac{v_{c,t+1}^i}{v_{c,t}^i} \exp \Delta c_{i,t+1}^i \quad i = h, f$$

We get the following formula:

$$(v_{c,t}^i)^\theta = E_t \left[ \delta e^{\Delta c_{i,t+1}^i(1-\gamma)} (1 + v_{c,t+1}^i)^\theta \right] \quad (A.1)$$

By imposing the steady state condition:

$$v_{c,t}^i = \delta \left( 1 + v_{c,s}^i \right)$$

$$v_{c,s}^i = \delta \frac{1}{1 - \delta}$$

Now we can proceed by linearizing around the steady state. Define:

$$F(\Delta c_{i,t+1}^i, v_{c,t+1}^i) = \delta e^{\Delta c_{i,t+1}^i(1-\frac{\delta}{1 - \psi})} (1 + v_{c,t+1}^i)$$

$$\frac{\partial F}{\partial \Delta c_{i,t+1}^i} |_{ss} = \delta \left( 1 - \frac{1}{\psi} \right) \left( 1 + \frac{\delta}{1 - \delta} \right)$$

$$\frac{\partial F}{\partial v_{c,t+1}^i} |_{ss} = \delta$$

Then we have:

$$v_{c,t}^i = E_t \left[ \delta + \frac{\delta}{1 - \delta} \left( 1 - \frac{1}{\psi} \right) \Delta c_{i,t+1}^i + \delta v_{c,t+1}^i \right]$$
Solve forward taking conditional expected value:

\[ v_{i,c,t}^i = \alpha_c + \beta_c x_{i,t}^i \]  \hspace{1cm} (A.2)

\[ \alpha_c = \frac{\delta}{1 - \delta} \]  \hspace{1cm} (A.3)

\[ \beta_c = \frac{\delta \left(1 - \frac{1}{\psi}\right)}{1 - \rho_x \delta} \]  \hspace{1cm} (A.4)

In a completely similar way:

\[ v_{i,d,t}^i = \alpha_d + \beta_d x_{i,t}^i \]  \hspace{1cm} (A.5)

\[ \alpha_d = \frac{\delta}{1 - \delta} \]  \hspace{1cm} (A.6)

\[ \beta_d = \frac{\delta \left(\lambda - \frac{1}{\psi}\right)}{1 - \rho_x \delta} \]  \hspace{1cm} (A.7)

We are ready to look at the returns, we will log-linearize the following expressions:

\[ R_{i,c,t}^j + 1 = \frac{v_{i,c,t}^j + 1}{v_{i,c,t}^j} \exp \Delta c_{i,t}^j \]  \hspace{1cm} (A.8)

\[ j = c, d \]

By using (A.8) and (A.2) we get:

\[ r_{i,j,t+1}^i = \Delta j_{i,t+1} + \log(1 + v_{j}^{ss}) + \frac{1}{1 + v_{j}^{ss}}(v_{j,t+1}^i - v_{j}^{ss}) - \log(v_{j}^{ss}) - \frac{1}{v_{j}^{ss}}(v_{j,t}^i - v_{j}^{ss}) \]  \hspace{1cm} (A.8)

\[ j = c, d \]

At this point it is possible to find the reduced form of the discount factor by plugging (A.9) and the law for the consumption growth back into (2). The log-s.d.f. assumes the following form:

\[ m_{t+1}^i = \log \delta - \frac{1}{\psi} x_{i,t}^i - \gamma c_{i,t+1}^i + \frac{\delta (1 - \gamma \Psi)}{\Psi (1 - \rho_x \delta)} x_{i,t+1}^i \]  \hspace{1cm} (A.10)

It follows that:
\[ V\text{ar}(\pi) = 2 \left[ \left( \frac{1}{\Psi} \right)^2 \frac{1}{1 - \rho_x^2} + \left[ \frac{\delta (1 - \gamma \Psi)}{\Psi (1 - \rho_x \delta)} \right]^2 \right] (1 - \rho_x^2) \sigma_x^2 + 2 \gamma^2 (1 - \rho_c^2) \sigma_c^2 \] 

(A.11)

and

\[ corr(m^h, m^f) = \left( \frac{1}{\Psi} \right)^2 \frac{1}{1 - \rho_x^2} \rho_x^2 \sigma_x^2 + \gamma^2 \sigma_c^2 \] 

(A.12)

Before starting to analyze the returns from the stocks let’s focus on several important moments regarding \( r_{c,t+1} \) and \( \Delta c_{i,t+1} \):

\[ V\text{ar}(r_{c,t+1}) = \left( \frac{1}{\Psi} \right)^2 \frac{1}{1 - \rho_x^2} + \left[ \frac{\delta (1 - \gamma \Psi)}{\Psi (1 - \rho_x \delta)} \right]^2 \sigma_x^2 + \sigma_c^2 \] 

(A.13)

\[ Cov(r_{c,t+1}, r_{f,t+1}) = \left( \frac{1}{\Psi} \right)^2 \frac{1}{1 - \rho_x^2} + \left[ \frac{\delta (1 - \gamma \Psi)}{\Psi (1 - \rho_x \delta)} \right]^2 \rho_x^2 \sigma_x^2 + \rho_c^2 \sigma_c^2 \] 

(A.14)

Assume the following process for dividends:

\[ \Delta d_{i,t+1} = \lambda x_i^t + \epsilon_{d,t+1} \] 

(A.17)

Now, by merging (A.5), (A.8), (A.17) we get:

\[ r_{d,t+1} = -\log(\delta) + \left( \frac{1}{\Psi} \right) x_i^t + \left[ \delta \left( \frac{\delta (\lambda - \psi)}{1 - \rho_x \delta} \right) \right] \epsilon_{x,t+1} + \epsilon_{d,t+1} \] 

(A.18)

We want to look also at the excess returns, so let us compute first the risk free rate in this economy. By using our NA condition:

\[ E_t \left[ \delta^{\theta} \exp -\frac{\theta}{2} \Delta c_{i,t+1} + (\theta - 1) r_{c,t+1} \right] = \frac{1}{1 + r_{free,t}} \] 

(A.19)

By using (A.19) and (A.9) we are in front of the following (approximated) condition:

\[ \delta^\theta E \left[ e^{N o r m a l \left( \frac{(1 - \theta) \log(\delta) - \frac{1}{2} \lambda \sigma_x^2 + \frac{\delta (1 - \theta) \delta (\gamma^2 \sigma_c^2 + [\delta (1 - \theta) \rho_x^2 \sigma_x^2 + \rho_c \rho_c \sigma_c^2]}{1 - \rho_x \delta} \right) } \right] = \frac{1}{1 + r_{free,t}} \]
Take logs:

\[
\ln(1 + r_{free,t}) = -\log(\delta) + \frac{1}{2} \left[ \gamma^2 \sigma^2_x + \left[ \delta \left( 1 - \frac{1}{\psi} \right) \frac{1}{1 - \rho_x \delta} \right]^2 \sigma^2_x \right] + \frac{1}{\psi} r_{t}
\]  \hspace{1cm} (A.20)

Notice that our risk free rate has the following variance:

\[
V(\ln(1 + r_{free})) = \left( \frac{1}{\psi} \right)^2 V(x^t) \hspace{1cm} (A.21)
\]

Now we can easily derive the expression for the excess returns:

\[
er_{t+1} \equiv \ln(1 + r_{d,t+1}) - \ln(1 + r_{free,t}) = -\frac{1}{2} \left[ \gamma^2 \sigma^2_x + \left[ \delta \left( 1 - \frac{1}{\psi} \right) \frac{1}{1 - \rho_x \delta} \right]^2 \sigma^2_x \right] + \left[ \delta \left( \lambda - \frac{1}{\psi} \right) \frac{1}{1 - \rho_x \delta} \right] \epsilon_{x,t+1} + \epsilon_{d,t+1}^t \hspace{1cm} (A.22)
\]

This implies that we have the following correlation across countries:

\[
corr(er_{t},er_{f}) = \frac{\delta \left( \lambda - \frac{1}{\psi} \right) \frac{1}{1 - \rho_x \delta} \sigma^2_x + \rho^2 \sigma^2_x \epsilon_{x,t+1} + \epsilon_{d,t+1}^t}{\left[ \delta \left( \lambda - \frac{1}{\psi} \right) \frac{1}{1 - \rho_x \delta} \right]^2 \sigma^2_x + \sigma^2_x} \hspace{1cm} (A.23)
\]

**Appendix B. Proof of Propositions**

**Proof of Proposition 1.**

The cross-country correlation of the stochastic discount factors is:

\[
corr(m_{t}^h,m_{t}^f) = \frac{\left( \frac{1}{\psi} \right)^2 \frac{1}{1 - \rho_x \delta} \sigma^2_x + \gamma^2 \rho^h \sigma^2_x + \left[ \frac{\delta (1 - \gamma \Psi)}{\Psi (1 - \rho_x \delta)} \right]^2 \rho \sigma^2_x \epsilon_{x,t+1}^t}{\left( \frac{1}{\psi} \right)^2 \frac{1}{1 - \rho_x \delta} \sigma^2_x + \gamma^2 \sigma^2_x + \left[ \frac{\delta (1 - \gamma \Psi)}{\Psi (1 - \rho_x \delta)} \right]^2 \sigma^2_x} \hspace{1cm} (B.1)
\]

For any choice of the parameters that satisfies the following two inequalities, $\rho_x \neq 1$ and $\rho_x \delta \neq 1$, the following three partial derivatives $\frac{\partial corr(m_{t}^h,m_{t}^f)}{\partial \rho^h}$, $\frac{\partial corr(m_{t}^h,m_{t}^f)}{\partial \psi}$, $\frac{\partial corr(m_{t}^h,m_{t}^f)}{\partial \rho_x}$ exist and are well defined. Let’s compute them and study their sign.

\[
\frac{\partial corr(m_{t}^h,m_{t}^f)}{\partial \rho_x^h} = \frac{\left( \frac{1}{\psi} \right)^2 \frac{1}{1 - \rho_x \delta} \sigma^2_x + \gamma^2 \rho^h \sigma^2_x + \left[ \frac{\delta (1 - \gamma \Psi)}{\Psi (1 - \rho_x \delta)} \right]^2 \sigma^2_x > 0 \hspace{1cm} (B.1)
\]

This derivative is positive for all the values of the parameters that respect the two conditions: $\rho_x \neq 1$ and $\rho_x \delta \neq 1$. This trivially implies that the correlation of the two stochastic discount factors is strictly increasing with respect to $\rho_x^h$. 

20
\[
\frac{\partial \text{corr}(m_t^h, m_t^f)}{\partial \Psi} = -\frac{2\gamma^2}{\Psi^2} \left[ \left( \frac{1}{\Psi} \right)^2 \frac{1}{1-\rho^2_x} + \frac{\delta^2(1-\gamma)}{(1-\rho_x\delta)^2} \right] \gamma^2 (\rho^h_x - \rho^h_c) \sigma^2_x \left( \frac{1}{\Psi} \right)^2 \frac{1}{1-\rho^2_x} \sigma^2_x + \gamma^2 \sigma^2_x + \left[ \frac{\delta(1-\gamma)}{(1-\rho_x\delta)\Psi^2} \right]^2 \sigma^2_x \right]^2 \]

(B.2)

When \( \rho^h_x = \rho^h_c \) this derivative is always zero, meaning that changes in \( \Psi \), \( \gamma \), or \( \delta \) do not affect the correlation of the two stochastic discount factors.

If \( \rho^h_x \neq \rho^h_c \), this derivative is zero only if

\[
\Psi = \frac{1}{\gamma} \delta
\]

(B.3)

where \( \delta = \frac{1-2\rho_x\delta+\delta^2}{\sigma^2_x(1-\rho_x\delta)} \). In particular, when \( \rho^h_x > \rho^h_c \) the sign of this derivative is positive for \( \Psi > \frac{1}{\gamma} \delta \) and negative for \( \Psi < \frac{1}{\gamma} \delta \).

Notice, finally, that

\[
\lim_{\delta \to 1-\gamma} \frac{1}{\gamma} \delta \geq 1
\]

(B.4)

and that

\[
\lim_{\rho_x \to 1-\gamma} \lim_{\delta \to 1-\gamma} \frac{1}{\gamma} \delta = \frac{1}{\gamma}
\]

(B.5)

So, for a high persistence of the long run component and an individual discount factor close to one, the minimum of the cross correlation of the two discount factors is achieved for \( \Psi = \frac{1}{\gamma} \), that is when the Epstein-Zin preferences collapse to the standard CES utility function.

\[
\frac{\partial \text{corr}(m_t^h, m_t^f)}{\partial \rho_x} = \frac{\gamma^2}{\Psi^2} \left[ \left( \frac{1}{\Psi} \right)^2 \frac{\rho_x}{(1-\rho^2_x)^2} + \frac{\delta^2(1-\gamma)}{(1-\rho_x\delta)^2} \right] \gamma^2 (\rho^h_x - \rho^h_c) \sigma^2_x \left( \frac{1}{\Psi} \right)^2 \frac{1}{1-\rho^2_x} \sigma^2_x + \gamma^2 \sigma^2_x + \left[ \frac{\delta(1-\gamma)}{(1-\rho_x\delta)\Psi^2} \right]^2 \sigma^2_x \right]^2
\]

(B.6)

When it exists, this derivative is always positive when \( \rho^h_x > \rho^h_c \), negative when \( \rho^h_x < \rho^h_c \) and null when \( \rho^h_x = \rho^h_c \). In the case in which \( \rho^h_x > \rho^h_c \) the cross correlation of the stochastic discount factors is strictly increasing with \( \rho_x \), so the minimum is achieved for \( \rho_x = 0 \).

When \( \rho^h_x \neq \rho^h_c \), the properties of these three derivatives jointly imply the existence of one unique minimizer in correspondence of \( \rho_x = 0 \), \( \rho^h_x = 0 \), \( \Psi = \frac{1}{\gamma} \delta \).

**Proof of Proposition 2.**

The variance of the depreciation rate is:

\[
\text{Var}(\pi) = 2 \left[ \left( \frac{1}{\Psi} \right)^2 \frac{1}{1-\rho^2_x} + \left[ \frac{\delta(1-\gamma)}{(1-\rho_x\delta)\Psi} \right]^2 \right] \left( 1-\rho^h_x \right) \sigma^2_x + \frac{2\gamma^2}{\Psi^2} \left( 1-\rho^h_c \right) \sigma^2_x
\]

(B.7)

The partial derivative of this expression with respect to \( \rho^h_x \) exists and is well defined for any value
of the other parameters provided that \( \rho_x \neq 1 \) and \( \rho_x \delta \neq 1 \):

\[
\frac{\partial \text{Var}(\pi)}{\partial \rho_x} = -2 \left[ \left( \frac{1}{\Psi} \right)^2 \frac{1}{1 - \rho_x^2} + \left[ \frac{\delta (1 - \gamma \Psi)}{\Psi (1 - \rho_x \delta)} \right]^2 \right] \sigma_x^2 \leq 0 \tag{B.8}
\]

In particular, when it exists, such a derivative is always negative implying that the volatility of the log-depreciation rate achieves its minimum when \( \rho_x = 1 \).
